Version: 1.0

Date: Feb. 18, 2023

Problem 1

Calculate and compare the expected value and standard deviation of price at time t (P_t). Given each of the 3 types of price returns, assuming $r_t \sim N(0, \sigma^2)$. Simulate each return equation using $r_t \sim N(0, \sigma^2)$ and show the mean and standard deviation match your expectations.

Answer

1. Mathematical Analysis

1. Classical Brownian Motion:

Model:

$$P_t = P_{t-1} + r_t$$

1. Time period = 1 (a.k.a given P_{t-1}):

$$E(P_t|P_{t-1}) = P_{t-1} + E(r_t) \xrightarrow{\mu=0} P_{t-1}$$

$$Var(P_t|P_{t-1}) = Var(P_{t-1} + r_t|P_{t-1}) = Var(r_t) = \sigma^2$$

2. Time period > 1 (a.k.a given P_0 and $t > 1$):

$$E(P_t|P_0) = E(P_0 + \sum_{i=1}^t r_i) = P_0 + \sum_{i=1}^t E(r_i) \xrightarrow{\mu=0} P_0$$

$$Var(P_t|P_0) = Var(P_0 + \sum_{i=1}^t r_i|P_0) = \sum_{i=1}^t Var(r_i) = t \cdot \sigma^2$$

2. Arithmetic Return:

Model::

$$P_t = P_{t-1} * (1 + r_t)$$

1. Time period = 1 (a.k.a given P_{t-1}):

$$E(P_t|P_{t-1}) = E(P_{t-1} * (1 + r_t)|P_{t-1}) = P_{t-1}(1 + E(r_t)) \xrightarrow{\mu=0} P_{t-1}$$

$$Var(P_t|P_{t-1}) = Var(P_{t-1} * (1 + r_t)|P_{t-1}) = P_{t-1}^2 Var(r_t) = P_{t-1}^2 \sigma^2$$

2. Time period > 1 (a.k.a given P_0 and $t>1$):

It's more complicated since the product of i.i.d normal random variables is not necessary to be normal.

$$E(P_t|P_0) = E(P_0 * \prod_{i=1}^t (1 + r_i)|P_0) = P_0 \cdot E(\prod_{i=1}^t (1 + r_i)) = ?$$

$$Var(P_t|P_0) = Var(P_0 * \prod_{i=1}^t (1 + r_i)|P_0) = P_0^2 \cdot Var(\prod_{i=1}^t (1 + r_i)) = ?$$

However, we could guess its distribution when the t is large due to central limit theorem.

$$\begin{aligned} \ln P_t|P_0 &= \ln P_0 + \sum_{i=1}^t \ln(1 + r_i)|P_0 \\ &= \ln P_0 + \sum_{i=1}^t \ln(1 + r_i) \xrightarrow{t \rightarrow \infty} N(\mu_{unknown}, \sigma_{unknown}^2) \end{aligned} \quad (1)$$

$$\Rightarrow P_t|P_0 \rightarrow LN(\mu_{unknown}, \sigma_{unknown}^2)$$

Therefore, $P_t|P_0$ would converge to lognormal ditribution.

3. Log Return(Geometric Brownian Motion):

Model: :

$$P_t = P_{t-1} e^{r_t}$$

1. Time period = 1 (a.k.a given P_{t-1}):

$$E(P_t|P_{t-1}) = E(P_{t-1} e^{r_t}|P_{t-1}) = P_{t-1} E(e^{r_t}) = P_{t-1} \cdot e^{\mu + \frac{\sigma^2}{2}} \xrightarrow{\mu=0} P_{t-1} \cdot e^{\frac{\sigma^2}{2}}$$

$$Var(P_t|P_{t-1}) = Var(P_{t-1} e^{r_t}|P_{t-1}) = P_{t-1}^2 \cdot Var(e^{r_t}) \xrightarrow{\mu=0} P_{t-1}^2 \cdot e^{\sigma^2} (e^{\sigma^2} - 1)$$

2. Time period > 1 (a.k.a given P_0 and $t>1$):

$$E(P_t|P_0) = E(P_0 e^{\sum_{i=1}^t r_i}|P_0) = P_0 E(e^{\sum_{i=1}^t r_i}) = P_0 e^{t\mu + \frac{t\sigma^2}{2}} \xrightarrow{\mu=0} P_0 \cdot e^{\frac{t\sigma^2}{2}}$$

$$Var(P_t|P_0) = Var(P_0 e^{\sum_{i=1}^t r_i}|P_0) = P_0^2 \cdot Var(e^{\sum_{i=1}^t r_i}) \xrightarrow{\mu=0} P_0^2 \cdot e^{t\sigma^2} (e^{t\sigma^2} - 1)$$

2. Numerical Validation & Results(Monte Carlo)

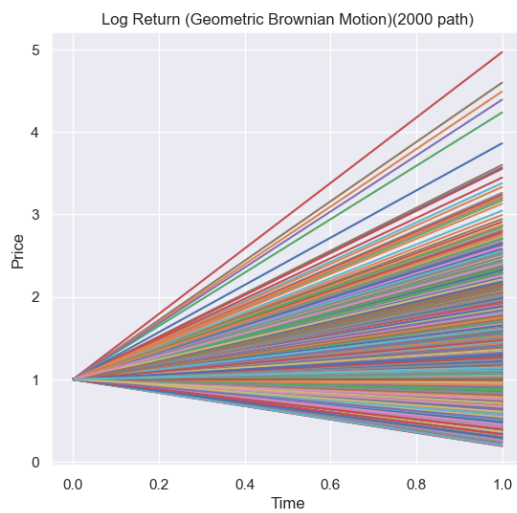

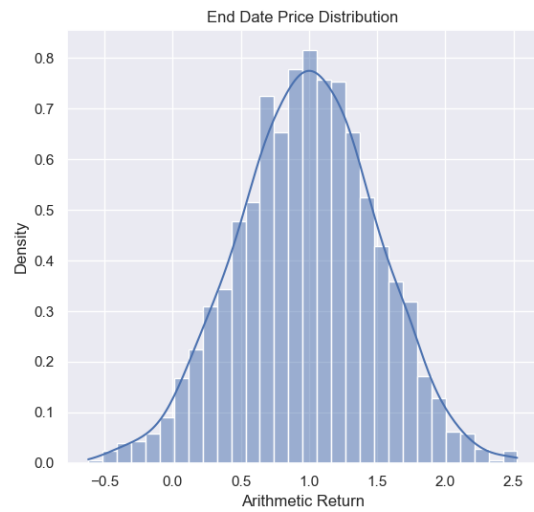

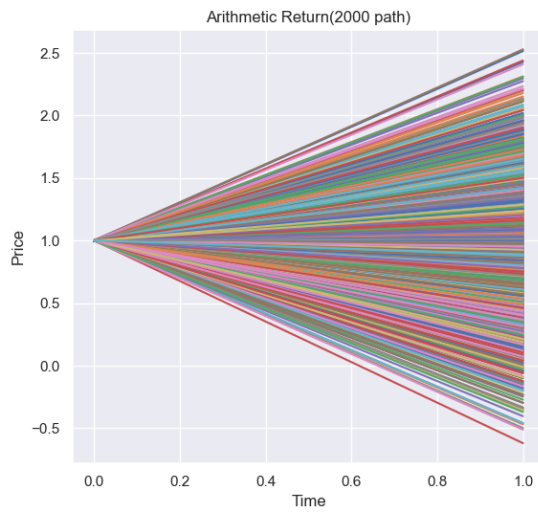

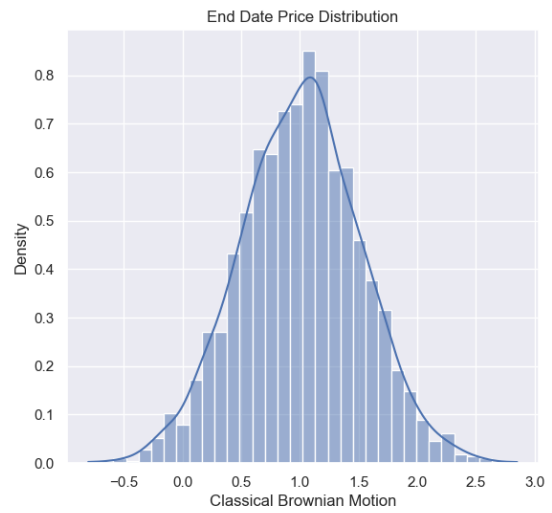

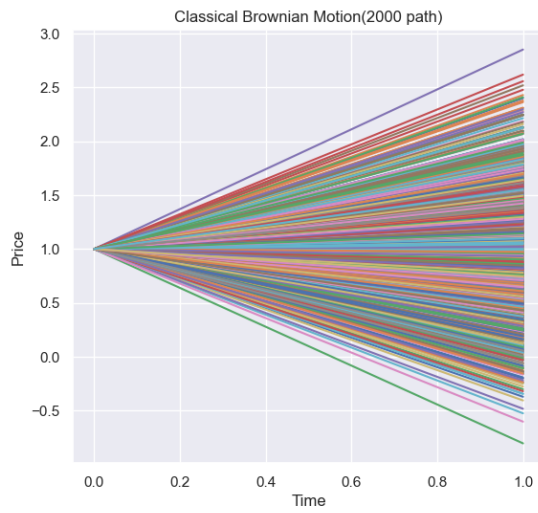

1. Time period = 1 (a.k.a given P_{t-1}):

We set the period to 1, the standard deviation σ to 0.5, the mean μ to 0, and the starting price to 1. After running the Monte Carlo 2000 times, we find that all of the estimated means and standard deviations match our expectations.

We can also see from the graph that when the period is 1, the end date price $P_t|P_{t-1}$ follows the normal distribution in the classical Brownian motion case and the arithmetic return case, but the end date price $P_t|P_{t-1}$ follows the lognormal distribution in the log return case.

Table 1: Time period = 1

Moments	Items	Classical Brownian Motion	Arithmetic Return	Log Return
Mean	Estimated	0.99486	1.00421	1.10918
	Expected	1	1	1.13315
Standard Deviation	Estimated	0.50691	0.50597	0.57477
	Expected	0.5	0.5	0.6039

2. Time period > 1 (a.k.a given P_0 and $t>1$):

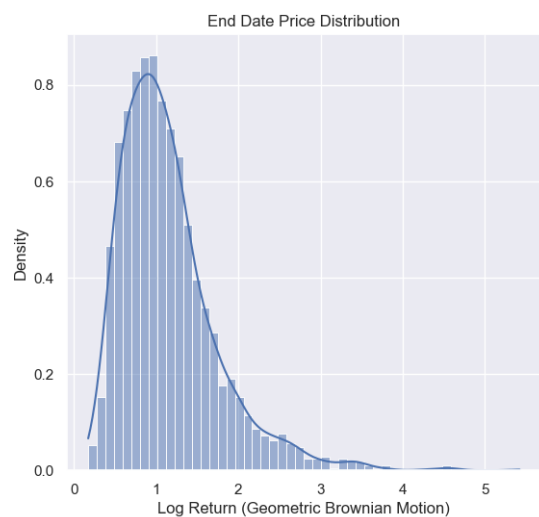

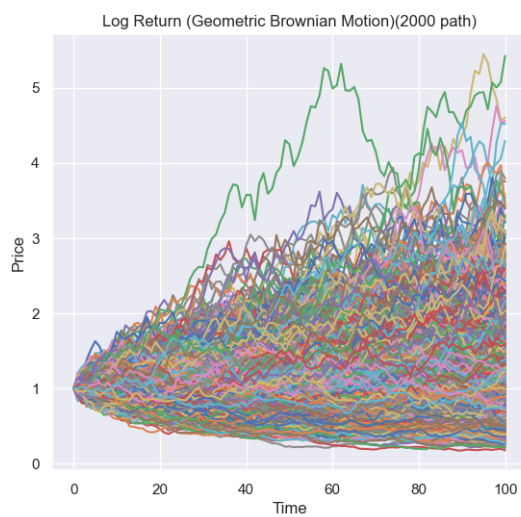

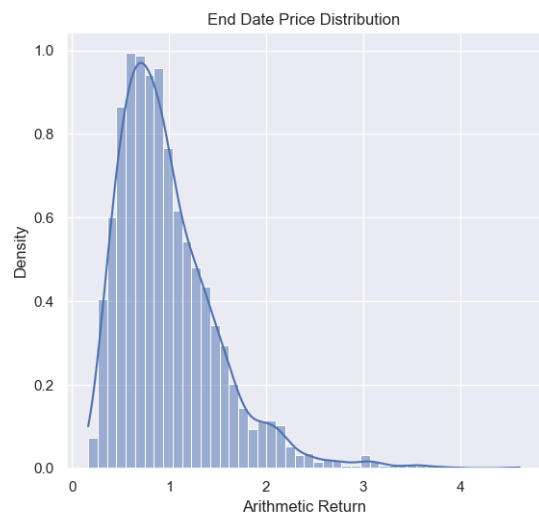

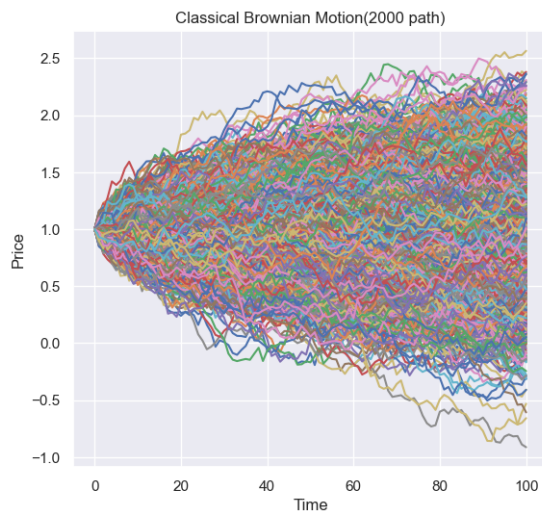

Now let's make the time period larger to see what happens. We set the time period to 100, the standard deviation σ to 0.05, the mean μ to 0, and the starting price to 1. Running the Monte Carlo 2000 times, we can see that for the Classical Brownian Motion case and the Log Return case, their estimated means and standard deviations agree with our mathematical results. However, for the Arithmetic Return case, we don't know its exact distribution, and we couldn't get the exact mean and standard deviation to compare numerically.

If we look at the figure, we could quickly see that the closing price of the Arithmetic Return confirms our hypothesis. Its distribution is approaching a lognormal distribution. In the classical Brownian motion case, it's still normal. As to logarithmic return case, it's lognormal.

All of above results match our expectation and validate our hypothesis.

Table 2: Time period = 100

Moments	Items	Classical Brownian Motion	Arithmetic Return	Log Return
Mean	Estimated	1.00971	0.99468	1.13466
	Expected	1	NAN	1.13315
Standard Deviation	Estimated	0.50361	0.53675	0.62123
	Expected	0.5	NAN	0.6039

Problem 2

Implement a function similar to the “return_calculate” in this week’s code. Allow the user to specify the method of return calculation.

Use DailyPrices.csv. Calculate the arithmetic returns for all prices.

Remove the mean from the series so that the mean(META)=0.

Calculate VaR:

1. Using a normal distribution.
2. Using a normal distribution with an Exponentially Weighted variance $\lambda = 0.94$
3. Using a MLE fitted T distribution.
4. Using a fitted AR(1) model.
5. Using a Historic Simulation.

Compare the 5 values.

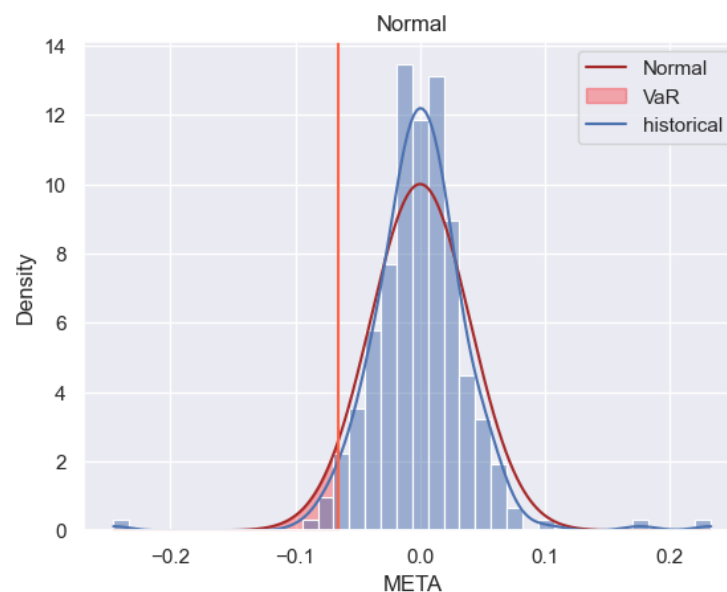

Answer

Use return_calculate function to get the return of each stocks then we use 5 methods to get VaR.

1. Normal Distribution

Assuming returns follow Normal Distribution whose mean is 0, we just need to calculate the standard deviation to understand the whole distribution. Then we get the VaR: **6.5601%**.

Compared with historical kernel density estimate, the normal returns has higher VaR and heavier tail.

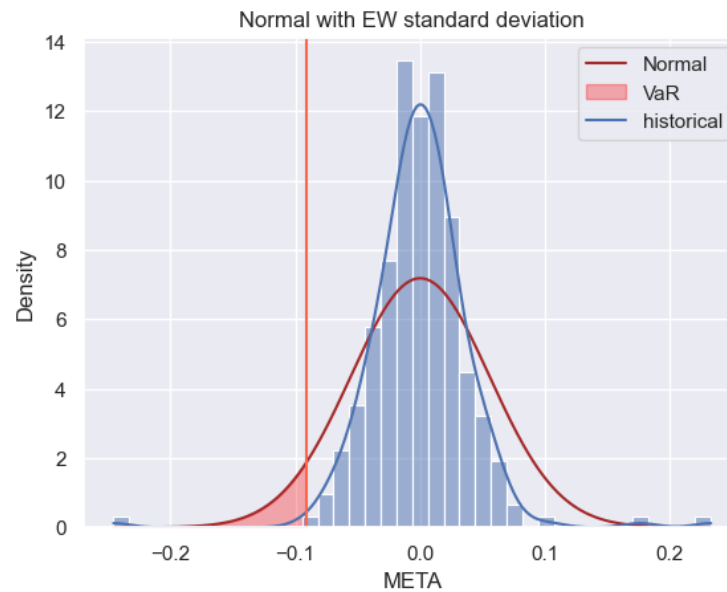

2. normal distribution with an Exponentially Weighted variance $\lambda = 0.94$

Assuming returns follow Normal Distribution whose mean is 0, we use differnet method to calculate the standard deviation. We put more weight on cuurent information to influence the construction of volatility. Then we get the VaR: **9.1385%**

Compared with historical kernel density estimate, the normal distribution with an Exponentially Weighted variance makes returns has much heavier tail than normal.

The reason why this may happen is because we put more weight on current information and recently volatility is higher than before.

3. MLE fitted T distribution

Assuming returns follow T distribution whose mean is 0, we use MLE to estimate its degree of freedom and variance to get the whole distribution. Then we get the VaR: **5.7256%**

As to T distribution, it's more sharp and its tail is thinner. Its VaR is lower than above estimator.

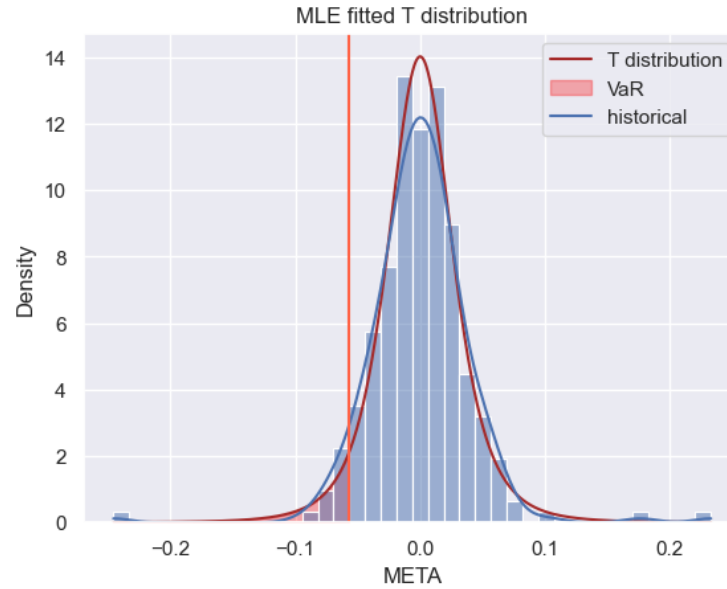

4. Fitted AR(1) model

Assuming returns follow AR(1) model, we use MLE to estimate its coffiience of Lag 1 and variance of its error term. After finish that, then we get the VaR: **6.5705%**

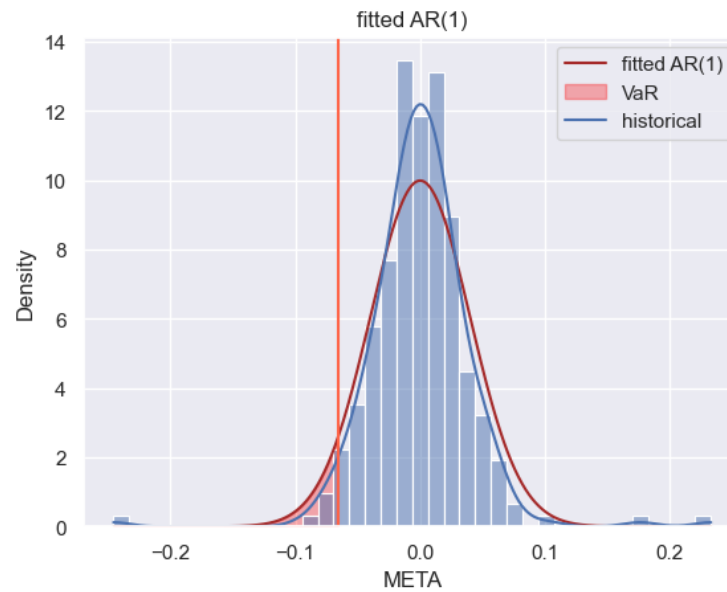

In fact, AR(1) model is normal distribution.

$$AR(1) : X_t = \phi_1 X_{t-1} + \varepsilon_t, \quad \{\varepsilon_t\} \sim WN(0, \sigma^2)$$

$$AR(1) : X_t = \varepsilon_t + \phi_1 \varepsilon_t + \phi_1^2 \varepsilon_t + \dots \sim WN(0, \frac{1}{1 - \phi_1^2} \sigma^2)$$

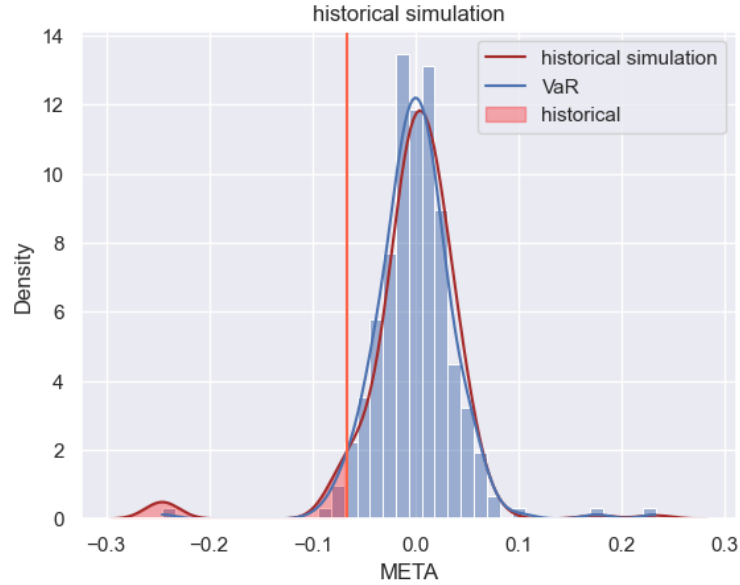

With such knowledge, it makes sense that its curve is so similar to Normal Distribution. Also, its VaR is little higher than historical estimator.

5. Historic Simulation

We fetch sample from the previous return data and simulate. Then then we get the VaR: **6.1604%**
Its curve is almost same as historical kernel density estimate.

Conclusion:

If we put all the VaRs on the same chart, we could see that Normal+EWMA has the most VaR and MLE fitted T has the least VaR.

I think the real VaR is between Normal+EWMA VaR and Historical Simulation VaR. Historical Simulation has no assumption of return distribution, but it averages its weights equally to each day. Normal+EWMA gives more weight to more recent information. The market is always changing and it makes sense to pay more attention to the current situation. Combining these two, we could estimate the real VaR.

Table 3: VaR of each method

	Normal	Normal+EWMA	MLE fitted T	AR(1)	Historical Simulation
VaR	6.5601%	9.1385%	5.7256%	6.5705%	6.1604%

Problem 3

Using Portfolio.csv and DailyPrices.csv. Assume the expected return on all stocks is 0.

This file contains the stock holdings of 3 portfolios. You own each of these portfolios. Using an exponentially weighted covariance with $\lambda = 0.94$, calculate the VaR of each portfolio as well as your total VaR (VaR of the total holdings). Express VaR as a \$

Discuss your methods and your results.

Choose a different model for returns and calculate VaR again. Why did you choose that model? How did the model change affect the results?

Answer

1. normal distribution with an Exponentially Weighted variance $\lambda = 0.94$

1.1 Delta Normal Method

Since our asset is stock, which means that its derivative on the price is just 1, it's easy for us to calculate the VaR using a closed-form formula. We calculate the VaR of Portfolio A, B, C and all of them as a whole separately. Let's look at the following results:

Table 4: VaR of Portfolio

	portfolio A	portfolio B	portfolio C	Total portfolio
VaR	5670.20	4494.59	3786.58	13577.07

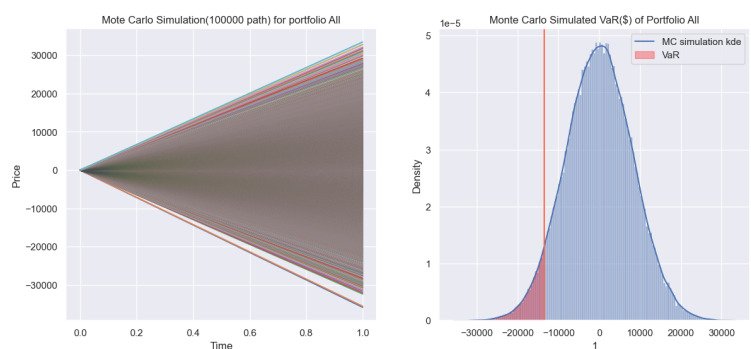

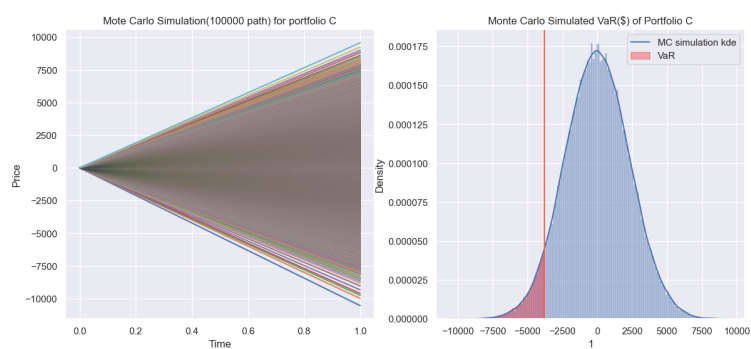

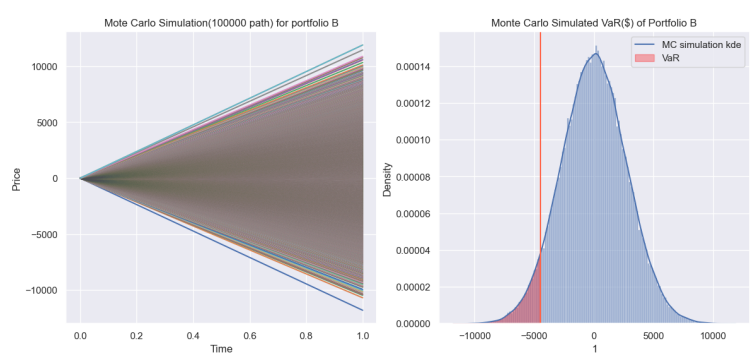

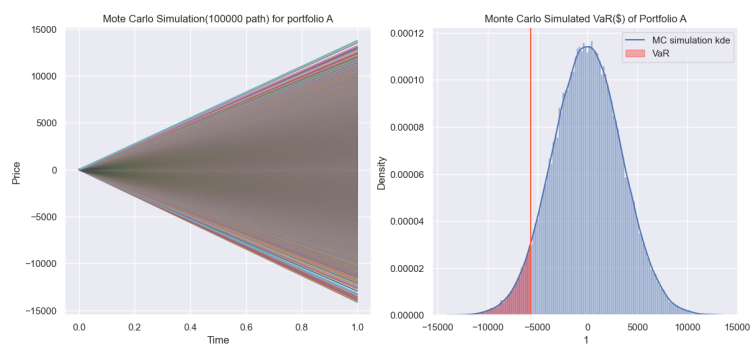

Portfolio A has the highest VaR, so its risk is the highest. We could see from the above chart that risk of A is greater than B, C, risk of B is higher than C.

1.2 Normal Monte Carlo

Then, we could also use EWMA covariance and PCA Normal Monte Carlo to generate simulated returns. Use those return we calculate the simulated price of each stock and combine them together to get the simulated value of portfolio. Here is results:

Table 5: VaR of Portfolio

	portfolio A	portfolio B	portfolio C	Total portfolio
VaR	5678.98	4492.44	3775.87	13570.22

We found that the VaR calculated by Delta Normal and Normal Monte Carlo are very close. These two methods validate each other.

For Delta Normal, if we add up the VaR of A,B,C, we could find it to be equal to 13951.37, which is greater than the VaR of the entire portfolio.

For Normal Monte Carlo, if we add up the VaR of A,B,C, we could find it equal to 13947.27, which is also greater than the VaR of the entire portfolio.

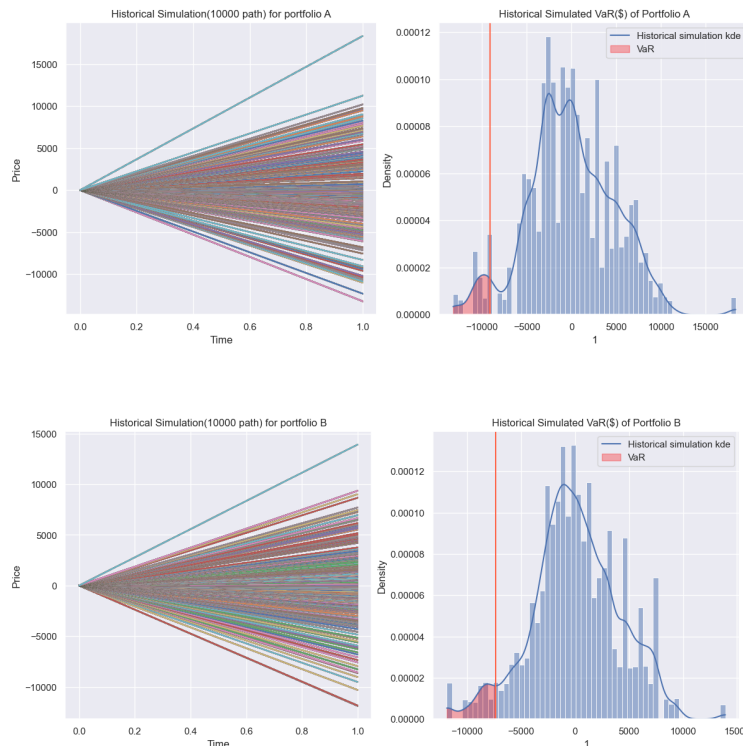

The above analysis shows that VaR doesn't have subadditivity, so it is not a coherent risk measure.

2. Historic Simulation

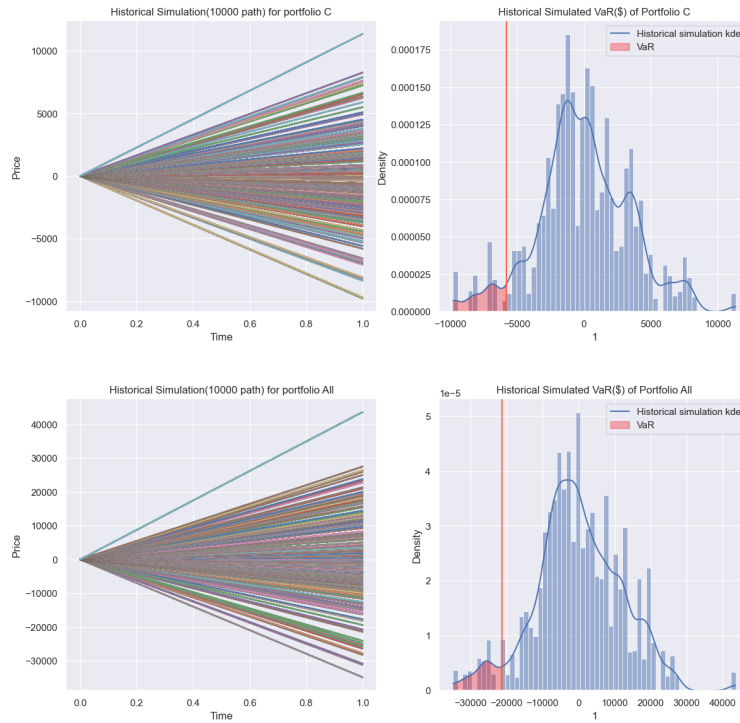

Since Historic Simulation has no assumption of the distribution of returns, its more reliable and logical. Here is result:

Table 6: VaR of Portfolio

	portfolio A	portfolio B	portfolio C	Total portfolio
VaR	9070.10	7351.16	5802.652	21275.01

We could see that the historical VaR is much larger than the above estimator. It indicates that the normal assumption underestimates the probability of extreme events. In other words, the normal distribution cannot capture the heavy tail of the real return distribution.

I prefer historical VaR because it's easy to implement and use. However, if we don't have enough data, it would have more bias.
